Abstract

Linear-optical passive (LOP) devices and photon counters are sufficient to implement universal quantum computation with single photons, and particular schemes have already been proposed. In this paper we discuss the link between the algebraic structure of LOP transformations and quantum computing. We first show how to decompose the Fock space of N optical modes in finite-dimensional subspaces that are suitable for encoding strings of qubits and invariant under LOP transformations (these subspaces are related to the spaces of irreducible unitary representations of $U(N)$). Next we show how to design in algorithmic fashion LOP circuits which implement any quantum circuit deterministically. We also present some simple examples, such as the circuits implementing a cNOT gate and a Bell state generator/analyser.

Keywords: linear optics quantum computation, single-photon multi-qubit encoding, linear-optical passive device, Jordan–Schwinger map

1. Introduction

Since the early times of quantum computing (QC) and quantum information processing (QIP), several proposals for implementation schemes have come from the field of quantum optics [1].

Quite recently, see [2], it has been shown that, at least in principle, *scalable-nondeterministic* quantum computation can be achieved by linear-optical passive (LOP) devices, exploiting also the nonlinearity introduced by conditional measurements [3–5]. This has led to several schemes [6–12] and experimental demonstrations [13–19] of quantum gates and circuits, which exploit different ways to encode a *single qubit* by a *single photon*: the qubit basis states can be encoded by the vacuum and the one-photon Fock states $\{|0\rangle, |1\rangle\}$ of a given mode of the quantized e.m. field [20], or by two orthogonal polarization states of a photon $\{|H\rangle, |V\rangle\}$, or by the one-photon Fock states of a two-mode optical system $\{|01\rangle, |10\rangle\}$.

On the other hand, the possibility of *deterministic-non-scalable* linear-optical quantum computing has been also pointed out, see [21, 22], and fundamental gates have been experimentally tested [23, 24]. These works rely on *single-photon multi-qubit* (SPMQ) encoding schemes, namely schemes that allow one to encode, say, k qubits by a single photon, by introducing $2^k - 1$ vacuum optical modes.

The aim of the present paper is twofold: first, in section 2, we show that the SPMQ encoding stems in a natural way from simple general features of the fundamental algebraic objects associated with the description of the quantized e.m. field and of LOP devices; then, in section 3, we make use of this result to introduce a simple algorithmic procedure which, for any given quantum computation, allows one to design the LOP circuit that implements it deterministically. We also briefly discuss the issue of scalability. Then, in section 4, we present some basic examples of deterministic LOP circuits.

2. Algebraic tools

In this section we introduce the algebraic formalism necessary to describe a quantum system of N optical modes, and the LOP devices acting on it; our aim is to highlight the algebraic structure underlying the implementation of QIP and QC by linear optics.

2.1. Heisenberg–Weyl algebra and Fock space

We start by briefly recalling the algebraic description of the physical system of a single-quantum optical mode, i.e. a vibrational mode of fixed frequency of the quantized e.m. field, that is formally equivalent to a quantum harmonic oscillator.

The fundamental object of this description is the *Heisenberg–Weyl algebra* $\mathcal{W}(1)$, namely the complex Lie algebra with generators $\{a, a^\star, e\}$ satisfying the relations

$$\begin{aligned} [a, a^\star] &= e, \\ [a, e] &= 0 = [a^\star, e], \end{aligned} \quad (1)$$

where $[\cdot, \cdot]$ denotes the Lie bracket. Notice that $\mathcal{W}(1)$ is a \star -algebra, since it is endowed with the involution \star , namely the antilinear map determined by

$$a \mapsto a^\star, \quad a^\star \mapsto (a^\star)^\star = a, \quad e \mapsto e^\star = e. \quad (2)$$

The algebra $\mathcal{W}(1)$ admits a remarkable realization—a realization which will be still denoted by $\mathcal{W}(1)$ in the following—as an algebra of operators in an infinite-dimensional Hilbert space \mathcal{H}_F (with the Lie bracket realized by the commutator):

$$a \mapsto a, \quad a^\star \mapsto a^\dagger, \quad e \mapsto \mathbb{I}, \quad (3)$$

where a^\dagger is the Hilbert space adjoint of a and \mathbb{I} is the identity operator. In fact, given an orthonormal basis $\{|n\rangle\}_{n=0}^\infty \subset \mathcal{H}_F$, one can define the *annihilation operator* a by

$$a|n\rangle = \sqrt{n}|n-1\rangle \quad \text{for } n \geq 1, \quad a|0\rangle = 0. \quad (4)$$

It follows that the *creation operator* a^\dagger satisfies

$$a^\dagger|n\rangle = \sqrt{n+1}|n+1\rangle \quad n = 0, 1, \dots; \quad (5)$$

moreover, one can define the *number operator* $\hat{n} \doteq a^\dagger a$,

$$\hat{n}|n\rangle = n|n\rangle, \quad n = 0, 1, \dots, \quad (6)$$

which is a positive self-adjoint operator.

Then, one can easily verify that

$$[a, a^\dagger] = \mathbb{I}, \quad (7)$$

hence, $\{a, a^\dagger, \mathbb{I}\}$ generate indeed a realization of the Heisenberg–Weyl algebra. The infinite-dimensional Hilbert space \mathcal{H}_F —endowed with the orthonormal basis $\{|n\rangle\}_{n=0}^\infty$ and the associated operator algebra generated by $\{a, a^\dagger, \mathbb{I}\}$ —is called *one-mode* (bosonic) *Fock space*.

The operator realization of $\mathcal{W}(1)$ can also be introduced in a more abstract way. In fact, let a be a linear operator in a (complex separable) Hilbert space \mathcal{H}_F satisfying relation (7). It is then possible to prove that, if, in addition, $\{a, a^\dagger\}$ is an

irreducible set of operators (i.e. any non-trivial linear span which is invariant under the action of a and a^\dagger must be dense in \mathcal{H}_F) and a technical condition concerning the operator $\hat{n} \doteq a^\dagger a$ is verified [25], the Hilbert space \mathcal{H}_F must be infinite dimensional and the operators a, a^\dagger are unitarily equivalent to the standard annihilation and creation operators of the harmonic oscillator in $L^2(\mathbb{R})$; moreover, the unitary operator that generates this unitary equivalence is uniquely defined up to an arbitrary phase factor. This is one of the formulations of the Stone–von Neumann theorem on canonical commutation relations [26, 27]. As a consequence, there is an orthonormal basis $\{|n\rangle\}_{n=0}^\infty$ (defined uniquely up to an overall phase factor) in \mathcal{H}_F such that (4) is satisfied; hence, one recovers the previous definition of the operator realization of $\mathcal{W}(1)$.

The operators a, a^\dagger defined in such a abstract way play respectively the role of annihilation and creation operators of the quantized e.m. field, and \hat{n} is then the photon-number operator.

Finally, we notice that \mathcal{H}_F can be decomposed in a natural way as the direct sum of subspaces characterized by a given number of photons:

$$\mathcal{H}_F = \bigoplus_{n=0}^{\infty} \mathcal{H}_n, \quad \mathcal{H}_n = \text{span}\{|n\rangle\} = \{\alpha|n\rangle : \alpha \in \mathbb{C}\}. \quad (8)$$

This formalism can be extended to the general case of N optical modes. The fundamental object becomes the algebra $\mathcal{W}(N)$, which is realized as the subspace of the linear space $\mathcal{W}(1)^{\otimes N}$ generated by the basis elements $\{a_i, a_i^\dagger, \mathbb{I}\}_{i=1}^N$, where

$$a_i = \mathbb{I} \otimes \dots \otimes \mathbb{I} \otimes \overbrace{a}^i \otimes \mathbb{I} \otimes \dots \otimes \mathbb{I}, \quad (9)$$

satisfying the canonical commutation relations:

$$[a_i, a_j^\dagger] = \delta_{ij} \mathbb{I}, \quad i, j = 1, 2, \dots, N. \quad (10)$$

The Hilbert space of this realization is the *N -mode* (bosonic) *Fock space* $\mathcal{H}_F^{(N)} \doteq \mathcal{H}_F^{\otimes N}$ endowed with the orthonormal basis $\{|n_1 \dots n_N\rangle : n_1, \dots, n_N = 0, 1, \dots\}$, with

$$|n_1, \dots, n_N\rangle = \left(\prod_{i=1}^N \frac{(a_i^\dagger)^{n_i}}{\sqrt{n_i!}} \right) |0\rangle. \quad (11)$$

Notice in passing that, if $N \geq 2$, the set of operators $\{a_i, a_i^\dagger, \mathbb{I}\}$, for any $i \in \{1, \dots, N\}$, now generates a *reducible* realization of $\mathcal{W}(1)$.

Notice also that, on the other hand, the operators $\{a_i, a_i^\dagger\}_{i=1}^N$ indeed form an irreducible set, and, according to the Stone–von Neumann theorem, any other irreducible set of operators $\{b_i, b_i^\dagger\}_{i=1}^N$ satisfying the canonical commutation relations (10) must be related to the set $\{a_i, a_i^\dagger\}_{i=1}^N$ by a unitary equivalence; precisely, there is a unitary operator U in $\mathcal{H}_F^{(N)}$, *uniquely defined up to an arbitrary phase factor*, such that

$$a_i = U b_i U^\dagger, \quad a_i^\dagger = U b_i^\dagger U^\dagger. \quad (12)$$

The Hilbert space $\mathcal{H}_F^{(N)}$ can be decomposed as

$$\mathcal{H}_F^{(N)} = \bigoplus_{n=0}^{\infty} \mathcal{H}_n^{(N)}, \quad (13)$$

where $\mathcal{H}_n^{(N)}$ is the subspace characterized by a given number n of photons, i.e.,

$$\mathcal{H}_n^{(N)} = \text{span}\{|n_1 \dots n_N\rangle : n_1 + \dots + n_N = n\}. \quad (14)$$

These subspaces are the eigenspaces of the ‘total number of photons operator’, i.e. of the positive self-adjoint operator

$$\hat{n} = \sum_{i=1}^N a_i^\dagger a_i. \quad (15)$$

Decomposition (13) plays a central role in understanding linear-optical quantum computing, and we will characterize it in the following by means of the bosonic realization of the Lie algebra $\mathfrak{u}(N)$ of $U(N)$ that is obtained via the Jordan–Schwinger map.

2.2. The Jordan–Schwinger map

In QIP and QC one always deals with finite-dimensional Hilbert spaces; indeed, information is represented by *words* over some finite *alphabet*, namely by finite strings of symbols, and in the quantum domain these symbols are realized by *qubits* or, more generally, by *qudits*. From a mathematical point of view, a *logical* qudit is a vector in a d -dimensional abstract Hilbert space, and strings of symbols are obtained through the tensor product structure.

On the other hand, when dealing with quantum optical systems one works with the *infinite-dimensional* Fock space. Nevertheless, we will show that by means of the Jordan–Schwinger (J–S) map, one can single out in a natural way suitable *finite-dimensional* subspaces that allow one to encode qudits and to represent the appropriate class of transformations that allow one to ‘move within’ these subspaces, namely to represent the action of quantum logic gates.

The general formulation of the J–S map [28–31] gives a simple procedure allowing one to obtain the so-called *bosonic realization* of a Lie algebra. Consider an operator realization of the $\mathfrak{gl}(N)$ algebra, with basis elements given by $\{d_{ij} \doteq a_i^\dagger a_j : i, j = 1, \dots, N\}$:

$$[d_{ij}, d_{mn}] = \delta_{jm} d_{in} - \delta_{ni} d_{mj}. \quad (16)$$

Now, consider an M -dimensional matrix Lie algebra \mathcal{A} , and a basis $\{A_k\}_{k=1}^M$ of \mathcal{A} of, say, $N \times N$ matrices ($M \leq N^2$).¹ Due to the properties of the operator realization of $\mathcal{W}(N)$, one can define the linear operators

$$Q_k = \sum_{ij} (A_k)_{ij} d_{ij} = \sum_{ij} a_i^\dagger (A_k)_{ij} a_j, \quad k = 1, \dots, M, \quad (17)$$

associated with the natural action of the matrices $\{A_k\}_{k=1}^M$ on the linear span of a_1, \dots, a_N . The linear operators $\{Q_k\}_{k=1}^M$ provide a basis of the N -dimensional ‘bosonic realization’ \mathcal{Q} of \mathcal{A} since, as the reader may verify using relations (16), the operators $\{Q_k\}_{k=1}^M$ preserve the commutation rules of the basis matrices $\{A_k\}_{k=1}^M$:

$$[Q_k, Q_l] = \sum_{ij} ([A_k, A_l])_{ij} d_{ij}, \quad k, l = 1, \dots, M. \quad (18)$$

¹ Recall that, by Ado’s theorem, any finite-dimensional complex Lie algebra is isomorphic to a subalgebra of $\mathfrak{gl}(N) \equiv \mathfrak{gl}(N, \mathbb{C})$ for some N .

The one-to-one correspondence $A_k \mapsto Q_k, k = 1, \dots, M$ —*extended by linearity*—is the J–S map: $\text{JS} : \mathcal{A} \rightarrow \mathcal{Q}$.

As a first example, let us construct the bosonic realization of the Lie algebra of the group $U(2)$. To this aim, we have to consider the composite system of two optical modes. Its Fock space $\mathcal{H}_F^{(2)}$ can be decomposed as in (13), with

$$\mathcal{H}_n^{(2)} = \text{span}\{|n, 0\rangle, |n-1, 1\rangle, \dots, |0, n\rangle\}. \quad (19)$$

Making use of the J–S map, it can be shown that these are the spaces of the irreducible unitary representations of the group $U(2)$ (or, also, of the group $SU(2)$).

Indeed, consider $\mathcal{A} = \mathfrak{u}(2)$ and its matrix realization generated by the 2×2 identity matrix Id and by the Pauli matrices $\sigma_1, \sigma_2, \sigma_3$; the generators of the bosonic realization of $\mathfrak{u}(2)$ are then obtained applying formula (17):

$$\begin{aligned} J_1 &\doteq \text{JS}(\tfrac{1}{2}\sigma_1) = \tfrac{1}{2} \begin{pmatrix} a_1^\dagger & a_2^\dagger \\ 0 & 0 \end{pmatrix} \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \begin{pmatrix} a_1 \\ a_2 \end{pmatrix} \\ &= \tfrac{1}{2}(a_1 a_2^\dagger + a_1^\dagger a_2), \\ J_2 &\doteq \text{JS}(\tfrac{1}{2}\sigma_2) = \tfrac{1}{2} \begin{pmatrix} a_1^\dagger & a_2^\dagger \\ 0 & 0 \end{pmatrix} \begin{pmatrix} 0 & i \\ -i & 0 \end{pmatrix} \begin{pmatrix} a_1 \\ a_2 \end{pmatrix} \\ &= \tfrac{i}{2}(a_1^\dagger a_2 - a_1 a_2^\dagger), \\ J_3 &\doteq \text{JS}(\tfrac{1}{2}\sigma_3) = \tfrac{1}{2} \begin{pmatrix} a_1^\dagger & a_2^\dagger \\ 0 & 0 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \begin{pmatrix} a_1 \\ a_2 \end{pmatrix} \\ &= \tfrac{1}{2}(a_1^\dagger a_1 - a_2^\dagger a_2), \\ \hat{n} &\doteq \text{JS}(\text{Id}) = \begin{pmatrix} a_1^\dagger & a_2^\dagger \\ 0 & 0 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} a_1 \\ a_2 \end{pmatrix} \\ &= (a_1^\dagger a_1 + a_2^\dagger a_2), \end{aligned} \quad (20)$$

where one can verify that the standard ‘angular momentum commutation rules’ are satisfied:

$$[J_i, J_j] = i\epsilon_{ijk} J_k, \quad (21)$$

with ϵ_{ijk} denoting the Levi Civita tensor, and $[J_k, \hat{n}] = 0$. The action of the operator J_3 and of the Casimir operator

$$\mathbf{J}^2 = J_1^2 + J_2^2 + J_3^2 = \frac{\hat{n}}{2} \left(\frac{\hat{n}}{2} + 1 \right) \quad (22)$$

on the Fock states, i.e.,

$$\mathbf{J}^2 |n_1 n_2\rangle = \frac{n_1 + n_2}{2} \left(\frac{n_1 + n_2}{2} + 1 \right) |n_1 n_2\rangle, \quad (23)$$

$$J_3 |n_1 n_2\rangle = \frac{n_1 - n_2}{2} |n_1 n_2\rangle, \quad (24)$$

gives rise to a relabelling of these states as eigenstates of the abstract angular momentum:

$$|n_1 n_2\rangle = |j, l\rangle \quad (25)$$

where

$$j = \frac{n_1 + n_2}{2} \quad \text{and} \quad l = \frac{n_1 - n_2}{2}, \quad (26)$$

² We follow the physicists’ convention for the Lie algebra $\mathfrak{u}(N)$; as a consequence an imaginary unit will appear in the argument of the exponential map from the algebra onto the group $U(N)$.

so that the subspaces $\{\mathcal{H}_n^{(2)}\}_{n=0}^\infty$ in (19) are the spaces of the $(2j+1)$ -dimensional unitary irreducible representation of the $U(2)$ group:

$$\mathcal{H}_n^{(2)} = \text{span}\{|j, j\rangle, |j, j-1\rangle, \dots, |j, -j\rangle\}, \quad j = \frac{1}{2}n, \quad (27)$$

with the index j identifying these subspaces, and the index $l = -j, \dots, j$ labelling the standard basis vectors in each subspace.

The generalization to the multimode case, with $N \geq 3$, can be outlined as follows. By means of the J–S map, the $u(N)$ generators can be realized as linear superpositions of the operators $\{a_i^\dagger a_j\}_{i,j=1}^N \subset \mathcal{W}(1)^{\otimes N}$. This makes it clear that the subspaces $\mathcal{H}_n^{(N)}$ of the N -mode Fock space $\mathcal{H}_F^{(N)}$ are invariant subspaces for the bosonic realization of the $u(N)$ generators: indeed, the action of the operators $\{a_i^\dagger a_j\}_{i,j=1}^N$ preserves the total number of photons. It follows that the n -photon space $\mathcal{H}_n^{(N)}$ can be decomposed as an orthogonal sum of spaces of irreducible unitary representations of $U(N)$. Actually, using the formalism of the ‘highest weights’ (see, for instance [32]), one can prove that, as in the special case of $U(2)$, the n -photon space $\mathcal{H}_n^{(N)}$ is the space of an irreducible unitary representation of $U(N)$ (hence, the mentioned orthogonal sum contains only one term). One can show, moreover, that, for $N \geq 3$, not all the irreducible representations of $U(N)$ can be realized in such a way; for instance, for $N = 3$, only the representations of dimension $\frac{1}{2}(n+1)(n+2)$, $n = 0, 1, \dots$, can be realized, while it is well known that the dimension of the irreducible unitary representations of $U(3)$ is given by the general formula

$$d = \frac{1}{2}(n_1+1)(n_2+1)(n_1+n_2+2), \quad n_1, n_2 = 0, 1, \dots \quad (28)$$

However, in what follows we will essentially deal with the *definitory* (or *fundamental*) representation of $U(N)$, whose Hilbert space is the single-photon N -mode space $\mathcal{H}_1^{(N)}$.

The characterization of $\mathcal{H}_1^{(N)}$ that we have given fits with the abstract definition of the Hilbert space of a quNit: an N -dimensional Hilbert space endowed with the fundamental representation of $U(N)$ acting on it. In the following, we will be specifically interested in the values of N given by $N = 2^k$, $k = 1, 2, \dots$. For these values of N , the following Hilbert space isomorphisms hold:

$$\mathcal{H}_1^{(2^k)} \cong (\mathbb{C}^2)^{\otimes k} \cong \mathcal{H}_1^{(2)} \otimes \dots \otimes \mathcal{H}_1^{(2)}, \quad (29)$$

with $(\mathbb{C}^2)^{\otimes k}$ regarded as an abstract qu $(N = 2^k)$ it, or, equivalently, as a k -qubit. However, we stress the following points:

- the Hilbert spaces respectively on the lhs and on the rhs of (29)—though mathematically isomorphic—have, for $k \geq 2$, a different physical meaning, since the former is a single-photon space while the latter is a k -photon space;
- this physical content has its mathematical counterpart in the fact that, for $k \geq 2$, the Fock space $\mathcal{H}_F^{(2^k)}$ is endowed with an irreducible operator realization of the algebra $\mathcal{W}(2^k)$, while the space $(\mathcal{H}_F^{(2)})^{\otimes k}$ is endowed just with k reducible operator realizations of $\mathcal{W}(2)$;

Figure 1. Generic LOP multiport. Horizontal lines represent optical modes entering and leaving the device, from left to right.

- accordingly, using the J–S map, one can endow $\mathcal{H}_1^{(2^k)}$ with the fundamental representation of $U(2^k)$, whereas, by the same procedure, only the fundamental representation of

$$U(2) \otimes \dots \otimes U(2) \subsetneq U(2^k) \quad (k \geq 2) \quad (30)$$

can be obtained (namely, $(\mathcal{H}_1^{(2)})^{\otimes k}$ is the space of k qubits which ‘do not interact’).

The previous observations are the basis of the SPMQ encoding and of the use of LOP transformation for the implementation of logic gates.

2.3. LOP transformations

We will now move to the description of the class of optical transformations which enable us to implement the *elaboration* of quantum information, namely logic gates on quNits.

The linear-optical *passive* (LOP) transformations (see e.g. the review paper [33]) are defined as the class of linear transformations that act on the system of N optical modes—i.e. of linear transformations in $\text{span}\{a_1 \dots a_N\}$ —leaving unchanged the total number of photons in the process; a generic LOP device is usually depicted as a $2N$ -port, namely a black box with N inputs and N outputs (figure 1), respectively corresponding to the field operators $\{a_i\}_{i=1}^N$ and $\{b_i\}_{i=1}^N$.

The property of photon-number conservation is expressed by the condition

$$\sum_i a_i^\dagger a_i = \sum_i b_i^\dagger b_i. \quad (31)$$

A simple calculation shows that this condition is sufficient to guarantee that the canonical commutation relations (10) still hold for the operators $\{b_i, b_i^\dagger, \mathbb{I}\}_{i=1}^N$, which thus form another basis for the realization of $\mathcal{W}(N)$, and can indeed be interpreted as the field operators of the output modes.

In fact, denoting by \underline{U} the matrix representing the LOP transformation,

$$b_i = \sum_j \underline{U}_{ij} a_j, \quad (32)$$

from condition (31) one can easily prove that

$$\underline{U} \underline{U}^\dagger = \underline{U}^\dagger \underline{U} = \text{Id}, \quad (33)$$

where Id is the identity matrix. Hence, with any LOP transformation there can be naturally associated a *unitary*

matrix \underline{U} ; conversely, any unitary matrix defines a LOP transformation. Thus, there is a one-to-one correspondence between LOP $2N$ -ports and the elements of the group $U(N)$.

On the other hand, formula (32) implies that any invariant linear span for the operators $\{b_i, b_i^\dagger\}_{i=1}^N$ must be invariant for the operators $\{a_i, a_i^\dagger\}_{i=1}^N$ as well, and this in turn means that the output field operators $\{b_i, b_i^\dagger\}_{i=1}^N$ form another irreducible set. Thus, as we have already pointed out in section 2.1, by the Stone–von Neumann theorem they must be unitarily equivalent to the operators $\{a_i, a_i^\dagger\}_{i=1}^N$, i.e.,

$$b_i = U^\dagger a_i U, \quad i = 1, \dots, N, \quad (34)$$

where U is a unitary operator in $\mathcal{H}_F^{(N)}$ uniquely defined up to an arbitrary phase factor.

Observe that, as a consequence of the photon-number conservation, the subspaces $\mathcal{H}_n^{(N)}$, $n = 0, 1, \dots$ of $\mathcal{H}_F^{(N)}$ are invariant subspaces for the operator U . In fact, using the definition of \hat{n} and condition (31), one can easily check that the unitary operator U commutes with \hat{n} :

$$\begin{aligned} U\hat{n} &= U\hat{n}U^\dagger U \\ &= \left(\sum_i U b_i^\dagger b_i U^\dagger \right) U \\ &= \sum_i a_i^\dagger a_i U \\ &= \hat{n}U. \end{aligned} \quad (35)$$

Then, since $\mathcal{H}_n^{(N)}$, $n = 0, 1, \dots$, is an eigenspace of \hat{n} , it must be an invariant subspace for U .

In particular, as $\mathcal{H}_0^{(N)} = \text{span}\{|0\rangle\}$, we have

$$U|0\rangle = e^{i\phi}|0\rangle, \quad (36)$$

for some $\phi \in \mathbb{R}$. We will now show that one can give an explicit form of the operator U in such a way that $e^{i\phi} = 1$. To this aim, consider the following recipe:

- write the matrix \underline{U} (associated with any LOP $2N$ -port) as the exponential of a matrix in the Lie algebra $\mathfrak{u}(N)$:

$$\underline{U} = e^{i\underline{J}}, \quad \underline{J} \in \mathfrak{u}(N); \quad (37)$$

- next, via the J–S map, one can obtain a self-adjoint operator J :

$$J = \text{JS}(\underline{J}) = \sum_{ij} \underline{J}_{ij} a_i^\dagger a_j; \quad (38)$$

- eventually one can define a unitary operator

$$U \doteq \exp(i\text{JS}(\underline{J})) = \exp\left(i \sum_{ij} \underline{J}_{ij} a_i^\dagger a_j\right). \quad (39)$$

We now claim that

- the unitary operator U verifies equation (32);
- the definition of U does not depend on the choice of a particular element \underline{J} of the algebra $\mathfrak{u}(N)$ such that $\exp(i\underline{J}) = \underline{U}$;

- the matrix $\tilde{U}_1^{(N)}$ representing the operator U in the one-photon subspace $\mathcal{H}_1^{(N)}$ of $\mathcal{H}_F^{(N)}$ is \underline{U} , precisely:

$$\begin{aligned} \langle 0, \dots, 0, \overbrace{1}^i, 0, \dots, 0 | U | 0, \dots, 0, \overbrace{1}^j, 0, \dots, 0 \rangle \\ = \underline{U}_{ij}. \end{aligned} \quad (40)$$

Indeed, let \underline{J} be a matrix in $\mathfrak{u}(N)$ and let us define the unitary operator U by formula (39). Then, using the well-known relation

$$e^{\hat{A}} \hat{B} e^{-\hat{A}} = \exp(\text{ad}_{\hat{A}}) \hat{B} \quad (41)$$

that holds for generic linear operators \hat{A}, \hat{B} (with $\text{ad}_{\hat{A}} \hat{B} \doteq [\hat{A}, \hat{B}]$), and applying the canonical commutation relations, one easily proves that

$$U^\dagger a_k U = \sum_l (e^{i\underline{J}})_{kl} a_l, \quad k = 1, \dots, N; \quad (42)$$

hence, for any \underline{J} satisfying $e^{i\underline{J}} = \underline{U}$, the operator U verifies equation (32).

Next, we prove that the association $\underline{U} \mapsto U$ defined by formula (39) does not depend on the choice of the matrix \underline{J} such that $e^{i\underline{J}} = \underline{U}$. To this aim, observe that—according to the Stone–von Neumann theorem—the operator U , which verifies equation (32), is uniquely identified by the phase factor $e^{i\phi}$ appearing in equation (36). Now, one can immediately check that, for any matrix $\underline{J} \in \mathfrak{u}(N)$, we have

$$\exp\left(i \sum_{k,l} \underline{J}_{kl} a_k^\dagger a_l\right) |0\rangle = |0\rangle; \quad (43)$$

hence, $e^{i\phi} = 1$ for U defined by formula (39) independently of the choice of \underline{J} such that $e^{i\underline{J}} = \underline{U}$. This proves that the definition of U itself does not depend on a particular choice of such a matrix \underline{J} , namely, our second claim.

Our third claim can be checked by an elementary calculation, by explicitly evaluating the lhs of equation (40):

$$\begin{aligned} \langle 0 | a_i U a_j^\dagger | 0 \rangle &= \langle 0 | U (U^\dagger a_i U) a_j^\dagger | 0 \rangle \\ &= \langle 0 | b_i a_j^\dagger | 0 \rangle \\ &= \sum_k \underline{U}_{ik} \langle 0 | a_k a_j^\dagger | 0 \rangle \\ &= \underline{U}_{ij}. \end{aligned} \quad (44)$$

(In the second line we used the fact that $U|0\rangle = |0\rangle$, $U^\dagger a_i U = b_i$.) Summarizing, we have shown that with any LOP $2N$ -port one can associate in a unique way two mathematical objects:

- a unitary matrix \underline{U} representing the LOP transformation: $b_i = \sum_j \underline{U}_{ij} a_j$;
- a unitary operator U uniquely identified by the equations

$$b_i = U^\dagger a_i U \quad i = 1, \dots, N, \quad U|0\rangle = |0\rangle. \quad (45)$$

Moreover, we have shown that one can give an explicit procedure for building the operator U from the matrix \underline{U} ; conversely, if the operator U is given, then the matrix \underline{U} can be obtained from relation (40).

We conclude by observing that the J–S map JS induces a map $\widehat{\text{JS}} : U(N) \rightarrow \mathcal{U}(\mathcal{H}_F^{(N)})$, where $\mathcal{U}(\mathcal{H}_F^{(N)})$ is the group of unitary operators in $\mathcal{H}_F^{(N)}$, defined by

$$\widehat{\text{JS}}(\underline{U}) = \widehat{\text{JS}}(\exp(i\underline{J})) = \exp(i\text{JS}(\underline{J})) = U. \quad (46)$$

Figure 2. LOP 2-port: phase-shifter.

Figure 3. LOP 4-port: beam-splitter.

Making use of the Stone–von Neumann theorem one can easily prove that

$$\widehat{JS}(\underline{U}_1 \underline{U}_2) = \widehat{JS}(\underline{U}_1) \widehat{JS}(\underline{U}_2), \quad (47)$$

for any $\underline{U}_1, \underline{U}_2 \in U(N)$, i.e. that \widehat{JS} is a unitary representation of $U(N)$.

2.4. Basic examples

Now we give an explicit form to the objects we have introduced so far, namely the matrix \underline{U} and the operator U , for two simple special cases: the 2- and the 4-port. They are indeed special because they are the only LOP devices directly implemented in the laboratories respectively by *phase shifters* (PS) and *beam splitters* (BS); then, any generic linear optical multiport can be implemented decomposing it as an array of 2- and 4-ports [34].

The simplest example is the PS, the LOP 2-port (figure 2) whose action is just the phase multiplication:

$$b = e^{+i\phi} a, \quad b^\dagger = e^{-i\phi} a^\dagger. \quad (48)$$

The group involved is $U(1)$, and its generator is simply $\underline{J} = 1$; in this case, the J–S map associates with \underline{J} the number operator, so that $J = a^\dagger a$, and

$$b = P^\dagger a P \quad \text{with } P(\phi) = e^{+i\phi \hat{n}}. \quad (49)$$

Notice that P acts on the Fock space \mathcal{H}_F as a photon-number-dependent phase factor.

A generic LOP 4-port (figure 3) is described by the 2×2 unitary matrix \underline{B} [35, 36]:

$$\underline{B} = e^{i\phi_0} \underline{B}' = e^{i\phi_0} \begin{pmatrix} e^{i\phi_\tau} \cos \theta & e^{i\phi_\rho} \sin \theta \\ -e^{-i\phi_\rho} \sin \theta & e^{i\phi_\tau} \cos \theta \end{pmatrix}; \quad (50)$$

the 4-port is implemented by PSs and BSs, respectively corresponding to the $U(1)$ factor and the $SU(2)$ matrix B' .

To obtain the operator representation of the BS's $SU(2)$ matrix, we consider the well-known Euler decomposition of a generic $SU(2)$ matrix as the product of three elementary

‘rotations’; then, recalling the bosonic realization of the $\mathfrak{su}(2)$ generators J_k , and the induced map \widehat{JS} , we can write

$$B'(\alpha, \beta, \gamma) = e^{-i\gamma J_z} e^{-i\beta J_y} e^{-i\alpha J_z}, \quad (51)$$

where $J_i = JS(\frac{1}{2}\sigma_i)$ are the linear combinations of the operators $\{a_i^\dagger a_j\}_{i,j=1}^N$ given by equations (20).

3. LOP schemes for deterministic quantum computation

In this section we apply the results of sections 2.2, 2.3 and derive a constructive procedure for building LOP circuits for deterministic quantum computation on an arbitrary number of qubits; then we discuss the issue of scalability.

3.1. Encoding: the SPMQ scheme

The encoding of (quantum) information is generally made possible by a more or less strict correspondence between the mathematical properties of the symbols that are chosen to represent the information, and those of the description of the physical system that is chosen to encode symbols. The case of SPMQ encoding is special from this point of view, since such a correspondence is indeed a complete equivalence in this case.

As we have already said, symbols in quantum information are represented by *quNits*; universal quantum computation can be done on strings of qubits in the common case of the binary coding. It is useful to recall the following abstract definitions:

- a *quNit* is a vector in a N -dimensional abstract Hilbert space, endowed with the fundamental representation of $U(N)$ acting on it;
- a *string of k qubits*, or *k -qubit*, is a vector in a 2^k -dimensional Hilbert space—specifically the tensor product of k copies of the two-dimensional single-qubit Hilbert space—endowed with the fundamental representation of $U(2^k)$ acting on it.

It should be clear from the results of section 2.2 that the mathematical characterization of $\mathcal{H}_1^{(N)}$ —the space of the states of a single photon over N optical modes—perfectly fits with the abstract definition of the *quNit* space; furthermore, choosing $N = 2^k$, one can say that $\mathcal{H}_1^{(2^k)}$ coincides with the previous abstract definition of the Hilbert space of a string of k qubits.

SPMQ encoding is the one-to-one correspondence between *logical states*—i.e. the states of a string of k abstract qubits—and the *physical states*—i.e. the states of the quantum system of a single photon over 2^k modes. The correspondence between logical and physical states can be formulated explicitly, using the well-known computational basis notation: if we denote by $\{|i\rangle\}_{i=1}^{2^k}$ the states of a given basis of the k logical qubits, we can rewrite them as column vectors with 2^k elements, which are all zero except for a 1 in the i th position, with $i = 1, \dots, 2^k$. Then, the SPMQ scheme consists in encoding the logical state $|i\rangle$ by the state of one photon in the i th mode, with $i = 1, \dots, 2^k$, and the corresponding notation is

$$\text{logical states} \longleftrightarrow \text{physical states}$$

$$|i\rangle \equiv \begin{pmatrix} 0 \\ \vdots \\ 0 \\ 1 \\ 0 \\ \vdots \\ 0 \end{pmatrix} |i\rangle \longleftrightarrow |0 \dots 0 \overbrace{1}^i 0 \dots 0\rangle = a_i^\dagger |0\rangle. \quad (52)$$

3.2. Elaboration: the algebraic scheme

We now claim that, with this encoding scheme, LOP devices are sufficient to implement deterministically any quantum circuit, without the need for ancillary resources and post-selection schemes [2].

As we have previously shown, with any LOP $2N$ -port one can associate a matrix in $U(N)$ acting on the input modes a_1, \dots, a_n , or equivalently a unitary operator U acting ‘by similarity’: $a_k \mapsto U^\dagger a_k U$. From the physical point of view, this is nothing but the action of the time evolution operator associated with the $2N$ -port (regarded as a quantum device) on the input field operators in the ‘Heisenberg picture’.

On the other hand, as far as applications to QIP and QC are concerned, since the encoding resource is given by the state vectors of the Fock space, it is convenient to switch to the ‘Schrödinger picture’ and to represent the action of the LOP devices (regarded as quantum logic gates) as the action of the associated unitary operators on the state vectors. The operator U can be represented by an infinite unitary matrix, after choosing a labelling of the Fock states; now we are interested in the action of U on the subspace $\mathcal{H}_1^{(N)}$, and, as shown in (44), this is represented by a $U(N)$ matrix $\tilde{U}_1^{(N)}$ which coincides with \underline{U} . Since we know that any $U(N)$ matrix \underline{U} corresponds to a LOP $2N$ -port built from an array of BSs and PSs [34], this means that we can act on $\mathcal{H}_1^{(N)}$ with any desired unitary transformation, and so we can do any quantum computation on a string of a fixed number of qubits.

To make the last statement more precise, once again we refer to the computational basis notation: recall that any logical quantum circuit acting on input strings of k logical qubits is represented by some unitary operator C acting on the k -qubit Hilbert space. After choosing a basis $\{|i\rangle\}_{i=1}^{2^k}$ for the logical states, the operator C associated with the circuit can be represented by a $2^k \times 2^k$ unitary matrix on such a basis:

$$(C)_{ij} \doteq \langle i|C|j\rangle; \quad (53)$$

this is the *computational basis matrix* of the quantum circuit.

Then, when using the SPMQ encoding, in order to design the LOP circuit which implements a given k -qubit quantum circuit, one just needs to follow three simple steps:

- (i) write down the computational basis matrix of the logical circuit;
- (ii) take the $(C)_{ij}$ as the matrix elements of the $\tilde{U}_1^{(N)} = \underline{U}$ matrix of a LOP circuit;
- (iii) apply the RZBB procedure [34] to decompose the \underline{U} matrix in the corresponding array of PSs and BSs.

This simple, constructive procedure for designing LOP quantum circuits constitutes the demonstration of the claim we made at the beginning of this section.

To conclude, notice that the simplicity of the procedure we presented makes it suitable for translation into an algorithm that could be run by a classical computer; furthermore, if BSs and PSs with variable parameters were available, their maximum number being fixed by the number of modes N , LOP components could be rearranged automatically in the appropriate configuration, thus making the design of LOP quantum circuit a completely automatized process.

3.3. The issue of scalability

LOP circuits for deterministic quantum computation can be designed when encoding strings of qubits by single-photon multimode states; but there are two practical problems related to this scheme.

- (i) The first one is the fact that, in order to encode a k -qubit state, we need 2^k optical modes, which means that an exponential amount of physical resource is required; this limits the practical feasibility of circuits acting on an arbitrary number of qubits.
- (ii) On the other hand, this scheme is deterministic only for computations executed on a fixed number of qubits: when coupling two registers, physical states of two photons will appear, which do not encode any logical state. Consider two strings of k_1 and k_2 qubits; these are encoded respectively on the spaces $\mathcal{H}_1^{(N_1)}$ and $\mathcal{H}_1^{(N_2)}$, where $N_i = 2^{k_i}$. The resulting physical system after a generic LOP transformation is the system of two photons on $N_1 + N_2$ modes, whose Hilbert space $\mathcal{H}_2^{(N_1+N_2)}$ is strictly larger than the encoding space $\mathcal{H}_1^{(N_1)} \otimes \mathcal{H}_1^{(N_2)}$.

At present stage it is not clear yet what the architecture of a quantum computer will be, but it seems reasonable that it will be a hybrid object made out of different components; in this regard, scalability is only one of the requirements to be satisfied, and it should not be considered so stringent as to rule out a proposal for the implementation. With the scheme we presented here, one can build circuits acting on a small number, e.g., 2 or 3, of qubits, which allow one to test experimentally with present technology some interesting QIP protocols, as we show in the next section. As a further remark, we point out a possible way to reduce the number N of optical modes necessary to encode k -qubit logical states, in such a way that N is polynomial in k . In fact, one could encode k -qubits in the subspace $\mathcal{H}_n^{(N)}$ of $\mathcal{H}_F^{(N)}$, with $n \geq 2$, and suitably exploit the irreducible representations of $U(N)$ acting in such subspaces for implementing logic gates.

With respect to the second problem, a solution could be found by means of a suitable post-selected circuit that allows one to reduce this deterministic non-scalable scheme to the non-deterministic scalable scheme proposed in [2], and *vice versa*.

4. Two-qubit deterministic circuits

We will first give some basic and simple examples of two-qubit gates³, and then a composite circuit for the generation

³ Here and in the following, the word *simple* refers to the intrinsic complexity of the proposed circuits, rather than to their concrete physical implementation which may require great care (e.g. for taking into account the various sources of errors).

and measurement of Bell states. To this aim, we write down explicitly the linear map that encodes logical two-qubit states by single-photon four-mode states, namely, in the Hilbert space $\mathcal{H}_1^{(4)}$. As for the notation, we will keep in mind the following scheme:

logical states	binary form	physical states	
$ 1\rangle \longleftrightarrow$	$ 00\rangle \longleftrightarrow$	$ 1000\rangle$	
$ 2\rangle \longleftrightarrow$	$ 01\rangle \longleftrightarrow$	$ 0100\rangle$	(54)
$ 3\rangle \longleftrightarrow$	$ 10\rangle \longleftrightarrow$	$ 0010\rangle$	
$ 4\rangle \longleftrightarrow$	$ 11\rangle \longleftrightarrow$	$ 0001\rangle$	

where, according to the conventional notation for k -qubit states, in the central column we have introduced the binary form of the logical states; we will use the binary notation for logical states in what follows.

4.1. cNOT

The first LOP circuit we present is a very simple one, implementing a cNOT gate. This is a two-qubit universal gate, i.e. it can be shown that the cNOT and arbitrary one-qubit gates are sufficient to build any quantum logic network. The cNOT gate acts on the logical computational basis by flipping the second (*target*) bit when the first (*control*) bit is equal to 1:

$$\begin{aligned}
 |00\rangle &\mapsto |00\rangle \\
 |01\rangle &\mapsto |01\rangle \\
 |10\rangle &\mapsto |11\rangle \\
 |11\rangle &\mapsto |10\rangle
 \end{aligned} \tag{55}$$

and it is represented by the following computational basis matrix:

$$\text{cNOT} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{pmatrix}. \tag{56}$$

Exploiting the following matrix identity,

$$\text{cNOT} = \tilde{U}_1^{(4)} = \underline{U}, \tag{57}$$

one can build the LOP circuit (figure 4) corresponding to \underline{U} : the decomposition in [34] is trivial in this case, since \underline{U} itself describes the transformation of a BS with 100% transmission (that is, a simple exchange) coupling modes 3 and 4. Note that only one single-photon source, three vacuum sources, and a classically controllable operation (the interchange of modes 3 and 4) are required, thus eliminating a possible source of errors due to non-ideal LOP components; the simplicity of this circuit is remarkable if one thinks that the cNOT is a basic gate that could be applied several times while running a quantum computation.

4.2. cPHASE

This gate appends a desired phase factor $e^{-i\phi}$ to the state $|11\rangle$, while leaving the other unchanged; it can be shown by a simple calculation that a cNOT transformation can be obtained by

Figure 4. LOP cNOT.

Figure 5. LOP cPHASE.

Figure 6. LOP SWAP.

a cPHASE with $\phi = \pi$ (also called cSIGN) preceded and followed by a suitable transformation of the target qubit.

The cPHASE is represented by the matrix

$$\text{cPHASE} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & e^{-i\phi} \end{pmatrix}; \tag{58}$$

also in this case decomposition is trivial, and the corresponding LOP circuit requires only one PS with $\phi = \pi$ acting on the fourth mode, as depicted in figure 5.

4.3. SWAP gate

This is the gate that interchanges the logical state of the two qubits, represented by the matrix

$$\text{SWAP} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \tag{59}$$

and it corresponds to a sequence of three alternate cNOTs. But within this scheme it is not necessary to implement this sequence: it suffices to note that the SWAP matrix interpreted as a LOP matrix describes a BS with 100% transmission coupling modes 2 and 3, which corresponds to the simple circuit shown in figure 6.

4.4. Bell state production and analysis

Many QIP protocols, for example quantum teleportation [40], rely on the use of entangled states of qubits as a resource, and

Figure 7. LOP circuit for Bell state generation (running from left to right) and measurement (from right to left). The two BSs are balanced, and produce a sign change on reflection off the lower face.

on the ability to distinguish among such states, thus leading to many efforts towards the production and detection of entangled physical states. Bell states are defined as the four maximally entangled states of a two-qubit system; within the scheme of QC they can be produced by means of a circuit composed by a cNOT preceded by a Hadamard gate on the control qubit: this maps the logical computational basis states onto the Bell states:

$$\begin{aligned}
 |00\rangle &\mapsto \frac{|00\rangle + |11\rangle}{\sqrt{2}} \\
 |01\rangle &\mapsto \frac{|01\rangle + |10\rangle}{\sqrt{2}} \\
 |10\rangle &\mapsto \frac{|00\rangle - |11\rangle}{\sqrt{2}} \\
 |11\rangle &\mapsto \frac{|01\rangle - |10\rangle}{\sqrt{2}}.
 \end{aligned} \tag{60}$$

By a simple calculation one finds that it is represented by the following matrix:

$$\text{cNOT} \cdot (H_1 \otimes \mathbb{I}_2) = \begin{pmatrix} \frac{1}{\sqrt{2}} & 0 & \frac{1}{\sqrt{2}} & 0 \\ 0 & \frac{1}{\sqrt{2}} & 0 & \frac{1}{\sqrt{2}} \\ 0 & \frac{1}{\sqrt{2}} & 0 & -\frac{1}{\sqrt{2}} \\ \frac{1}{\sqrt{2}} & 0 & -\frac{1}{\sqrt{2}} & 0 \end{pmatrix} \tag{61}$$

where H denotes the Hadamard gate, and index 1 refers to the fact that it acts on the first (control) qubit.

The implementation of a Bell state analyser in the framework of linear optics has been studied [37–39], leading to the result that a complete measurement in the qubit polarization Bell basis is not possible. Nevertheless, in the SPMQ scheme we are proposing, a simple LOP circuit for the simulation of Bell state production and analysis can be found that works deterministically: as in the previous examples, one just takes the matrix (61) as a LOP circuit matrix, decomposes it and obtains the circuit depicted in figure 7. Only two balanced (50% transmission) BSs, with a sign change upon reflection off the lower side, and interchange of modes 3 and 4 are required.

5. Conclusions and perspectives

In this paper we have considered some algebraic structures of linear optics, and discussed how they provide a natural way to deal with linear-optical quantum computing; on the other hand, we have stressed on the correspondence of such algebraic objects with the basic instruments used in the laboratories, to

point out that practical implementations can, in principle, be designed and tested.

As a result, we first derived an SPMQ scheme for encoding any number of qubits by only one photon; then, we described an algorithmic procedure which, given any logical quantum circuit, allows one to design the linear optical circuit which implements the logical circuit operation deterministically, and we presented some simple but interesting two-qubit gates and circuits.

We also discussed some practical problems related to the scalability of such scheme, and pointed out some possible solutions. However, it seems reasonable that in the future a quantum computer will be a composite object, which will exploit both scalable and non-scalable, both deterministic and non-deterministic components (most likely in association with classical components).

In this regard, it is interesting to test such components experimentally, and further work is to be done to quantify the effects of non-ideal instruments on the theoretical schemes. It should be noticed that the scheme proposed here requires no ancillary systems, namely additional photon sources and counters, which are the main sources of inefficiency; *only one* single-photon source is required, regardless of the number of qubits, and this should lead to an efficiency which is almost independent of the number of qubits.
